13. ABSTRACT (Maximum 200 words) Cell-extracellular matrix (ECM) interaction is important for cell differentiation in mammary epithelial cells. Previous reports suggest that $\alpha 2 \beta 1$ integrin, a collagen/laminin receptor, plays a critical role in normal mammary cell differentiation as well as in the pathogenesis of breast cancer. Therefore, the modulation of $\alpha 2 \beta 1$ -ligand interaction can be a key factor in controlling breast cancer differentiation. The purpose of this study is to clarify the role of $\alpha 2 \beta 1$ -ligand interaction in breast cancer differentiation, and to elucidate the molecular mechanism of $\alpha 2 \beta 1$ -ligand interaction. During the second year of this project, I found that several discontinuous amino acid residues surrounding the MIDAS (metal ion dependent adhesion site) motif in the $\alpha 2$ I(A) domain are critical for collagen binding. In contrast, mutation or deletion of the entire unique C-helix residues, which have previously been predicted to determine collagen binding specificity, did not affect collagen binding at all. We created a collagen/ $\alpha 2$ I domain docking model. In this model, Asn-154, Tyr-157, Asp-219, and His-258 make direct contact with collagen. These findings will form the basis for the remainder of this study.

## INTRODUCTION

Cell-extracellular matrix (ECM) interaction has a profound impact on cell structure and function. There is overwhelming evidence that the ECM influences mammary epithelial cell differentiation. Cell-ECM interaction is mediated through a variety of cell surface receptors including integrins. The  $\alpha 2\beta 1$  integrin, a collagen/laminin receptor, is expressed in mammary epithelial cells and plays a critical role in normal mammary cell differentiation as well as in the pathogenesis of breast cancer. Modulation of  $\alpha 2\beta 1$ -ECM interaction could affect mammary cell differentiation. Elucidation of  $\alpha 2\beta 1$ -ligand binding mechanisms may lead to the development of therapeutic interventions against breast cancer.

The ligand binding site(s) in  $\alpha 2\beta 1$  has been localized in the I (A) domain of the  $\alpha 2$  subunit. Although several amino acid residues that constitute the metal ion-dependent adhesion site (MIDAS) are critical for ligand binding, the specific contact site for each ligand is not well characterized. I focused my effort on identifying the specific amino acid residues that make direct contact with collagen. I found that multiple discontinuous amino acid residues surrounding the MIDAS motif make direct contact with collagen. Based upon the crystal structure of the  $\alpha 2$  I domain, I created a docking model of  $\alpha 2$  I domain and collagen triple helical peptide. Using the same strategy, I will be able to identify residues that make contact with recombinant laminin  $\alpha 1$  chain. Once the specific mutations that block either collagen or laminin are determined, I will express these mutations in a breast cancer cell line and examine their effect on differentiation. The information obtained in this study may form the basis for the development of therapeutic interventions against breast cancer.

## BODY - Annual Summary

### Discontinuous multiple amino acid residues in the I domain are required for collagen binding

The MIDAS face, the putative ligand binding face, of the  $\alpha 2$  I domain is composed of four discontinuous loop structures. The  $\beta A$ - $\alpha 1$ ,  $\alpha 3$ - $\alpha 4$ , and  $\beta D$ - $\alpha 5$  loops contain amino acid residues that compose the MIDAS motif, which is critical for divalent cation coordination. These amino acid residues are conserved relatively very well among different I domains. On the contrary, the amino acid sequences of the  $\beta E$ - $\alpha 6$  loop are variable. Notably, there are five amino acid insertions within this loop in collagen-binding  $\alpha 1$ ,  $\alpha 2$ , and  $\alpha 10$  integrin I domains (Fig. 1). The crystal structure of  $\alpha 2$  I domain reveals that these inserted residues constitute an extra C-helix within the  $\beta E$ - $\alpha 6$  loop. This C-helix creates a groove on top of the MIDAS face in which a collagen triple helix is predicted to dock. Therefore the C-helix is predicted to be the major determinant of collagen binding. I reported in the previous annual report that the collagen binding sites in  $\alpha 2\beta 1$  are localized in the three discontinuous loops ( $\beta A$ - $\alpha 1$  loop,  $\alpha 3$ - $\alpha 4$  loop, and  $\beta D$ - $\alpha 5$  loop) within the I domain of the  $\alpha 2$  subunit based on the results from  $\alpha 2/\alpha L$  loop-swapping mutagenesis. To further characterize the collagen-contact face, I introduced multiple point mutations into the residues within the  $\beta A$ - $\alpha 1$ ,  $\alpha 3$ - $\alpha 4$ ,  $\beta D$ - $\alpha 5$ , and  $\beta E$ - $\alpha 6$  loops. I stably expressed mutant  $\alpha 2$  in CHO cells and examined their binding to immobilized collagen type I. Consistent with the results from loop-swapping mutagenesis, I found that Ser-153, Ile-156, and Tyr-157 in  $\beta A$ - $\alpha 1$ ; Gln-215 and Gly-218 in  $\alpha 3$ - $\alpha 4$ ; and Gly-255 in  $\beta D$ - $\alpha 5$ , in addition to the previously reported Asp-151, Thr-221, and Asp-254, are critical for collagen binding. In addition, mutation of Asn-154, Ser-155, Asp-219, and His-258 had a mild blocking effect on collagen binding when collagen type I was immobilized at 2  $\mu\text{g/ml}$  (Fig. 2). Unexpectedly, mutations in the amino acid residues in the  $\beta E$ - $\alpha 6$  loop did not affect collagen binding at all. It is possible that several amino acid residues in the  $\beta E$ - $\alpha 6$  loop have to be mutated at the same time to detect their effect on collagen binding. To rule out this possibility, I created a deletion mutant that lacks most of the residues in the  $\beta E$ - $\alpha 6$  loop, including the entire C-helix. I generated a clonal CHO cell line expressing the mutant  $\alpha 2$  and examined its binding to plastic plates that had been coated with collagen type I at various concentrations. The del  $\alpha C$

mutant showed binding to collagen type I comparable with that of wild-type at all collagen immobilizing concentrations (Fig. 3). These results suggests that the del  $\alpha$ C mutant has a collagen-binding affinity comparable to that of wild-type  $\alpha$ 2; therefore the unique C-helix does not contain an energetically important collagen contact site. Instead, the collagen contact sites are localized in the relatively conserved sequences surrounding the MIDAS motif.

#### $\alpha$ 2 I domain/collagen binding model

In collaboration with Dr. Liddington, we created an  $\alpha$ 2 I domain/collagen docking model based on the current mutagenesis data. In the crystal structure, Asp-151, Ser-153, Ser-155, Thr-221, and Asp-254 are involved in the coordination of the cation. Ile-156 is totally buried in the molecule. Mutations of Gln-215, Gly-218, and Gly-255 are either buried or likely to disrupt the MIDAS motif. In contrast, Asn-154, Tyr-156, Asp-219, and His-258 are totally exposed on the surface of the molecule, suggesting that these residues make direct contact with collagen. Recently, a short synthetic triple-helical peptide, representing residues 502-516 of the collagen type I  $\alpha$ 1 chain, has been shown to support purified  $\alpha$ 2 $\beta$ 1 and recombinant  $\alpha$ 2 I-domain binding. The Glu and Arg residues in the GER triplet were found to be essential for recognition by the  $\alpha$ 2 I-domain. We first attached the glutamate side chain of the GER motif to the MIDAS  $Mg^{2+}$  ion, then rotated the collagen to minimize the distance between the collagen and those surface-exposed residues implicated in collagen binding (Asn-154, Tyr-157, Asp-219 and His-258) while maintaining the 2 Å bond between the glutamate oxygen and the  $Mg^{2+}$  ion and avoiding other close contact with the protein. In the current model, Asn-154, Tyr-157, Asp-219, and His-258 make direct contact with collagen, and the arginine from the GER motif makes a salt bridge to Glu-256 (Fig. 4). In addition, Tyr-285 from the C-helix also makes direct contact with collagen. However, current mutagenesis data suggest its not energetically important.

#### Recommendations in Relation to the Statement of Work

Thus far I have focused my effort on identifying the collagen contact site in  $\alpha$ 2 $\beta$ 1. Using the same strategy, I plan to identify the laminin-1 contact site using a recombinant laminin  $\alpha$ 1 chain. The collagen and/or laminin-binding-defective mutants produced will be useful for elucidating the role of cell-ECM interactions in breast cancer cell differentiation.

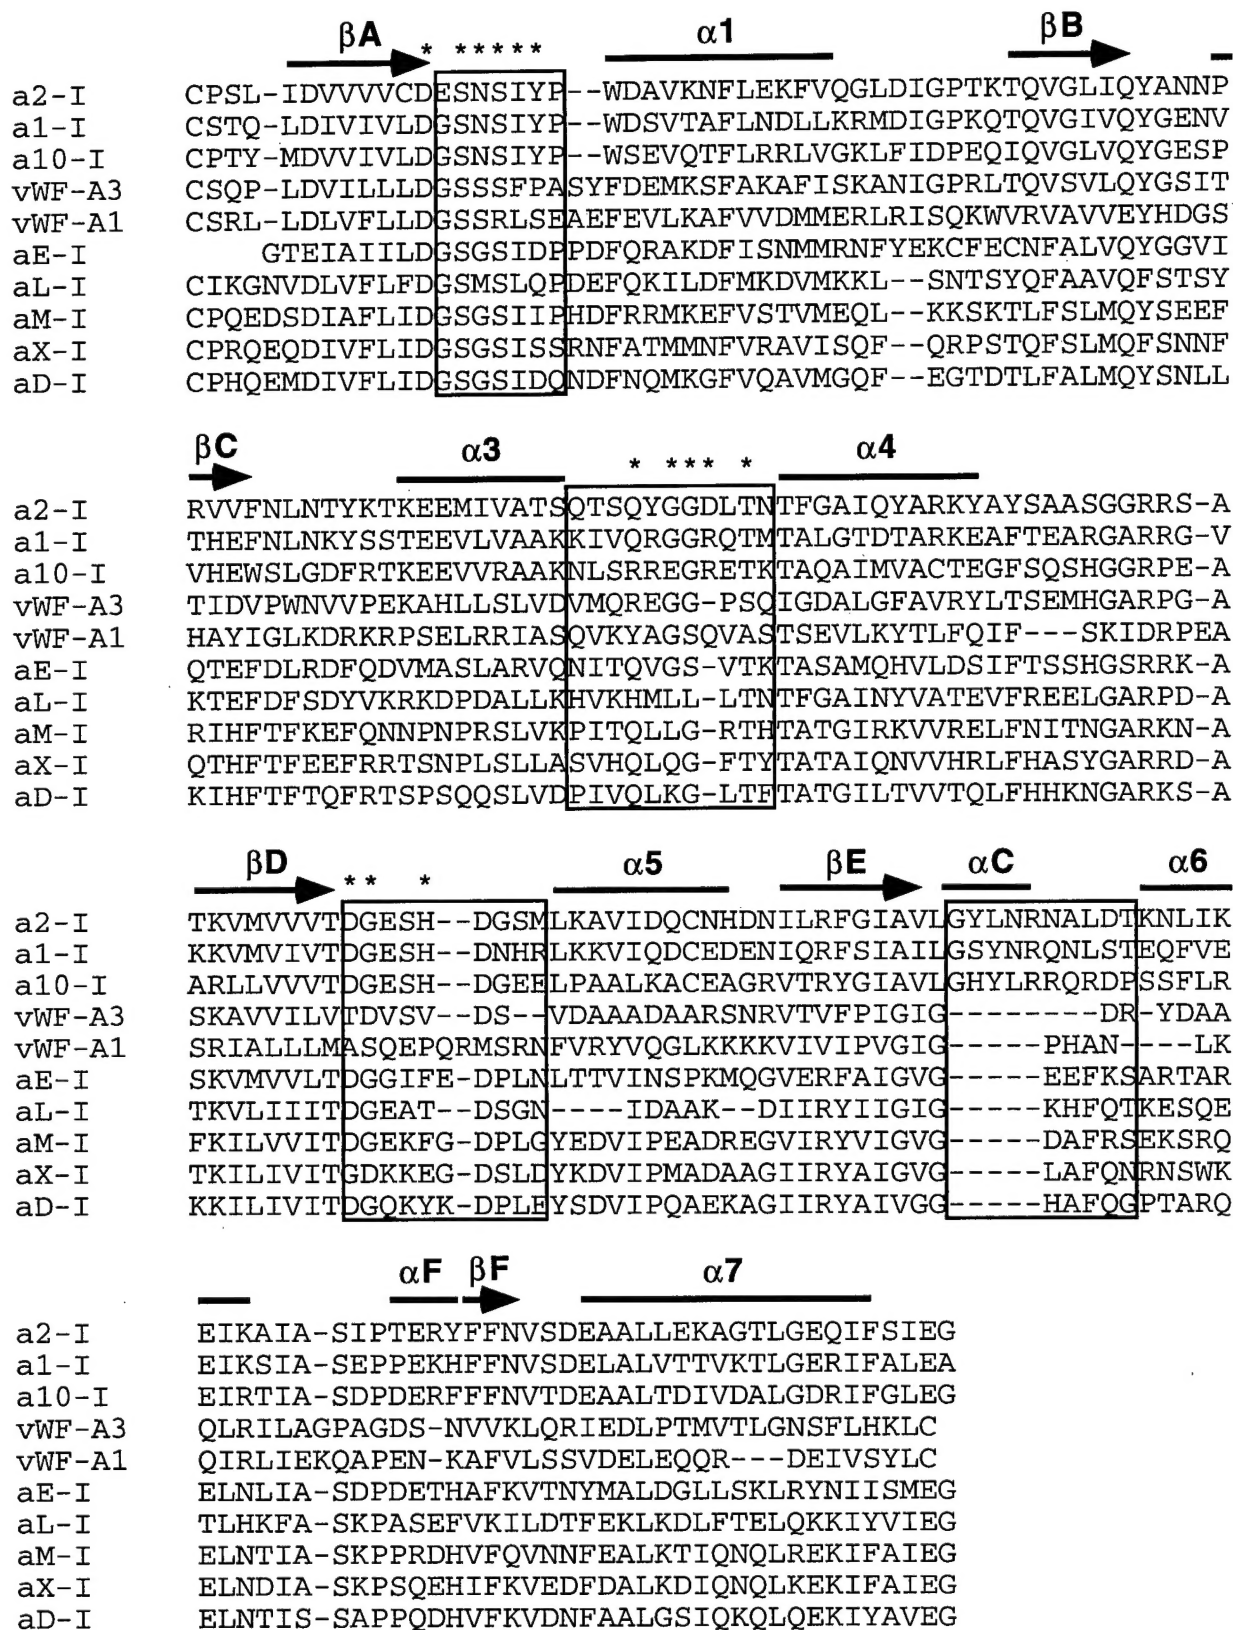

Fig. 1 Alignment of I-domains. The loops comprising the MIDAS motif (βA-α1, α3-α4, βD-α5) and the loop which includes αC helix (βE-α6) are outlined in boxes. The asterisks indicate amino acid residues critical for α2β1-collagen interaction.

Fig. 2 The effect of alanine mutations on the  $\alpha 2$ -expressing CHO cell adhesion to immobilized collagen type I. Amino acid residues were substituted with Ala.

CHO cells stably expressing wild-type (wt) or mutant  $\alpha 2$  were analyzed for expression of  $\alpha 2$  using FACS with HAS-4 and for adhesion to collagen type I that has been immobilized at 10  $\mu$ g/ml (■) or at 2  $\mu$ g/ml (▨). The data are expressed as a ratio of the percentage of collagen bound cells per the percentage of  $\alpha 2$  positive cells.

Fig. 3 The effect of del  $\alpha$ C mutation on  $\alpha$ 2 $\beta$ 1-collagen type I interaction. Cells were incubated for one hour in wells which has been precoated with different concentration of collagen type I. After washing, bound cells were quantitated by endogenous phosphatase assay.

Fig. 4 Docking model of the  $\alpha$ 2 I-domain and collagen

All-atom representation of the  $\alpha$ 2 I domain, viewed looking down onto the MIDAS face. The  $Mg^{2+}$  ion is labeled at the center of the molecule. The collagen molecule is shown as a triple helical coil drawn through the  $C\alpha$  positions. Asn-154, Tyr-157, Asp-219, His-258 and Tyr-285 are labeled.

## APPENDICES

Willebrand factor.

## ABSTRACT

A docking model of the  $\alpha 2$  I-domain and collagen has been proposed based on their crystal structures (Emsley, J., King, S., Bergelson, J. and Liddington, R. C., *J. Biol. Chem.*, 272, 28512-28517, 1997). In this model, several amino acid residues in the I-domain make direct contact with collagen (N154, D219, L220, E256, H258, Y285, N289, L291, N295, and K298), and the protruding C-helix of  $\alpha 2$  (residues 284-288) determines ligand specificity. Since most of the proposed critical residues are not conserved, different I-domains are predicted to bind to collagen differently. We found that deleting the entire C-helix or mutating the predicted critical residues had no effect on collagen binding to whole  $\alpha 2\beta 1$ , with the exception that mutating N154, D219, and H258 had moderate effect. We performed further studies and found that mutating the conserved surface-exposed residues in the MIDAS (Y157 and Q215) significantly blocks collagen binding. We have revised the docking model based on the mutagenesis data. In the revised model, conserved Y157 makes contact with collagen in addition to the previously proposed N154, D219, H258, and Y285 residues. These results suggest that the collagen-binding-I-domains (e.g.,  $\alpha 1$ ,  $\alpha 2$ , and  $\alpha 10$ ) bind to collagen in a similar fashion.

## INTRODUCTION

Several integrin  $\alpha$  chains ( $\alpha 1$ ,  $\alpha 2$ ,  $\alpha 10$ ,  $\alpha L$ ,  $\alpha M$ ,  $\alpha X$ ,  $\alpha D$ , and  $\alpha E$ ) have inserted I- or A- domains of about 200 amino acid residues (1-11)). Integrins  $\alpha 1\beta 1$  (1),  $\alpha 2\beta 1$  (reviewed in (12)), and  $\alpha 10\beta 1$  (4) have been shown to bind to collagen and/or laminin. Several function-blocking antibodies map to the I-domains of  $\alpha 2\beta 1$  (13) and  $\alpha 1\beta 1$  (14). The recombinant  $\alpha 2$  I-domain fragment binds to collagen (15,16), and the recombinant  $\alpha 1$  I-domain fragment binds to collagen and laminin (17). Conserved Asp and Thr residues in the  $\alpha 2$  I-domains (D151, T221, and D254) are critical for collagen binding (15). These lines of evidence suggest that the I-domain is critically involved in collagen binding.

The crystal structures of the I-domains of the integrin  $\alpha M$  (18),  $\alpha L$  (19), and  $\alpha 2$  (20) subunits, and the A1 (21,22) and A3 (23,24) domains of von Willebrand factor (vWf) have been published. This domain adopts a classic "Rossmann" fold and consists of a hydrophobic  $\beta$ -sheet in the middle and amphipathic  $\alpha$ -helices on both sides. Interestingly, the integrin I-domain contains a  $Mg^{2+}/Mn^{2+}$  coordination site at its surface, which is not present in proteins with similar structures (e.g., the NAD binding domain of lactate dehydrogenase) or the vWf A1 and A3 domains (21-24). The Asp and Thr residues in  $\alpha 2$  that have been shown to be critical for ligand binding are involved in the coordination of a divalent cation in the crystal structure (20). The  $\alpha 2$  I-domain has a unique helix (the C-helix) protruding from the metal ion dependent adhesion site (MIDAS) that creates a groove centered on the magnesium ion. Emsley et al. proposed a model in which a collagen triple helix fits into the groove, and a Glu side chain from collagen coordinates the metal ion. In this model, the C-helix is a major determinant

for collagen binding. It was as predicted that the following I-domain residues make direct contact with collagen: N154 (the  $\beta$ A- $\alpha$ 1 turn), D219 and L220 (the  $\alpha$ 3- $\alpha$ 4 turn), E256 and H258 (the  $\beta$ D- $\alpha$ 5 turn), and Y285, N289, L291, N295 and K298 (the C-helix,  $\alpha$ 6 and C- $\alpha$ 6 turn). However, these residues are not well conserved among collagen-binding I-domains (e.g.,  $\alpha$ 1,  $\alpha$ 2, and  $\alpha$ 10), suggesting that different I-domains interact with collagen in different manners. Here we show that mutation of the residues proposed to be critical for ligand binding or deletion of the entire C-helix did not significantly affect collagen binding to whole  $\alpha$ 2 $\beta$ 1 expressed on mammalian cells except for N154, D219, and H258. In contrast, mutating several conserved MIDAS residues including Y157 significantly blocks collagen binding. We have revised the docking model based on the mutagenesis data. In the revised model, interaction between the  $\alpha$ 2 I-domain and collagen is mediated by relatively conserved residues in the MIDAS on the N-terminal side of the I-domain. Thus, it is suggested that the collagen-binding I-domains (e.g.,  $\alpha$ 1,  $\alpha$ 2, and  $\alpha$ 10) bind collagen in a similar fashion.

## EXPERIMENTAL PROCEDURES

Monoclonal antibodies. HAS-3 and HAS-4 (25) are generous gifts from F. Watt (Imperial Cancer Research Fund, London, UK.)

### Adhesion of CHO cells to collagen.

Wells of 96 well microtiter plates (Immulon-2, Dynatech Labs., Inc., Chantilly, VA) were coated with type I collagen (2 or 10  $\mu\text{g/ml}$ ) at 4 °C overnight. The other protein binding sites were blocked by incubating with 1 % (w/v) bovine serum albumin (Calbiochem, CA) for 30 min at room temperature, and washing three times with PBS (10 mM phosphate, 0.15 M NaCl, pH 7.4). Cells were harvested with 3.5 mM EDTA in PBS and washed twice with Dulbecco's modified Eagle medium.  $10^5$  cells (in 100  $\mu\text{l}$  Dulbecco's modified Eagle medium) were added to each well and incubated for 1 h at 37 °C. The wells were rinsed three times with PBS to remove unbound cells. Bound cells were quantified by assaying endogenous phosphatase activity (26).

### Molecular modeling.

A model of a collagen triple helix was constructed from the crystal structure [(27), PDB entry 1cag] as previously described (20). Side-chains from the sequence of the CB3(I)5/6 peptide containing the GER motif (28) were grafted onto the collagen in standard conformations using the program TOM (29). The glutamate of one of the GER motifs was attached to the  $\text{Mg}^{2+}$  ion of the MIDAS motif via one of its carboxylate oxygens at a distance of 2.0 Å. Keeping the I-domain fixed, the collagen was then allowed to rotate around a fixed point (the glutamate oxygen) to minimize

the distance between the collagen and the side chains of those residues which showed reduced collagen binding when mutated and which were exposed on the surface of the I-domain. Unfavorably close contacts ( $< 2.5$  Å) between the collagen and the I-domain were monitored using the program TOM. Since the triple helical nature of collagen generates three chemically distinct strands even for a homo-tripeptide (which we call the leading, middle, and trailing strands) each of these was tested separately.

#### Other methods.

Swapping mutagenesis was carried out using the overlap extension polymerase chain reaction (30). The positions of the  $\alpha 2$  sequences replaced by homologous  $\alpha L$  sequences are residues 152-157, 212-219, and 257-262 (designated  $\beta A-\alpha 1$ ,  $\alpha 3-\alpha 4$ , and  $\beta D-\alpha 5$ , respectively)(Fig. 1). Deletion of residues 284-291 (designated  $\alpha C$  del) and point mutations were created by site-directed mutagenesis using the unique site elimination method with a double stranded vector (31). The presence of mutation was confirmed by DNA sequencing. Transfection of cDNAs into CHO cells by electroporation, selection of transfected cells with G418, immunoprecipitation, and flow cytometry were carried out as previously described (32).

## RESULTS AND DISCUSSION

The MIDAS of the  $\alpha 2$  I-domain is composed of four loops (the  $\beta A$ - $\alpha 1$ ,  $\alpha 3$ - $\alpha 4$ ,  $\beta D$ - $\alpha 5$ , and  $\beta E$ - $\alpha 6$  loops). The conserved residues D151 in the  $\beta A$ - $\alpha 1$  loop, T221 in the  $\alpha 3$ - $\alpha 4$  loop, and D254 in the  $\beta D$ - $\alpha 5$  loop are critical for cation coordination and ligand binding (13,15). A unique C-helix is inserted within the  $\beta E$ - $\alpha 6$  loop in the I-domains of the collagen-binding integrins  $\alpha 1$ ,  $\alpha 2$ , and  $\alpha 10$ , but is not present in the I-domains of  $\alpha M$  or  $\alpha L$ , or the A3 domain of vWf. This C-helix has been predicted to be a major determinant for collagen binding (20).

To identify the residues in the MIDAS that are critical for collagen binding, we introduced multiple point mutations into each MIDAS loop. We also included amino acid residues (N154, D219, L220, E256, H258, Y285, N289, L291, and N295) that have been predicted to make direct contact with collagen (20). Mutant  $\alpha 2$  was transfected into CHO cells together with a neomycin-resistant gene and selected for G-418 resistance. Cells stably expressing the mutant  $\alpha 2$  were used for adhesion assays. Fig. 2 shows the adhesion of the mutants to collagen type I expressed as a percentage of cells adherent to collagen per percentage of human  $\alpha 2$  positive cells (normalized adhesion to collagen). We found that mutating several residues in the  $\beta A$ - $\alpha 1$  loop (S153 and Y157) and the  $\alpha 3$ - $\alpha 4$  loop (Q215) blocks collagen binding. In addition, mutation of N154 and S155 in the  $\beta A$ - $\alpha 1$  loop, D219 in the  $\alpha 3$ - $\alpha 4$  loop, and H258 in the  $\beta D$ - $\alpha 5$  loop produced an inhibitory effect at lower collagen coating concentrations.

We also swapped the  $\beta A$ - $\alpha 1$  (residues 152-157),  $\alpha 3$ - $\alpha 4$  (residues 212-219), and  $\beta D$ - $\alpha 5$  loops (residues 257-262) with the corresponding sequences of  $\alpha L$ , which does not interact with collagen (Fig. 1). These

swapping mutations did not change the conserved residues D151, T221, and D254, which are critical for cation and collagen binding. Cells expressing mutant  $\alpha 2$  were tested for their ability to adhere to collagen. The expression of the  $\alpha 3$ - $\alpha 4$  swapping mutant was too low to produce reliable adhesion data (data not shown). Other mutants showed a surface-expression level comparable with that of wild type and reacted with multiple mAbs against  $\alpha 2$  (Fig. 3a). The  $\beta A$ - $\alpha 1$  swapping mutant showed collagen binding at a background-level. Also, the  $\beta D$ - $\alpha 5$  swapping mutant showed significantly reduced collagen binding. These results are consistent with those obtained using alanine-scanning mutagenesis.

In contrast, mutation of amino acid residues in the  $\beta E$ - $\alpha 6$  loop, including the C-helix, did not have any inhibitory effect on collagen binding. Mutation of Y285, N289, L291, and N295, which are predicted to make direct contact with collagen, did not significantly affect collagen binding, even at low (2  $\mu\text{g/ml}$ ) collagen coating concentrations (Fig. 2). It is possible that single amino acid substitution may not be enough to induce a detectable effect on collagen binding. So, we deleted most of the  $\beta E$ - $\alpha 6$  loop, including the entire C-helix, to determine whether the C-helix is critical for ligand specificity. These mutant  $\alpha 2$  cDNAs were stably expressed on CHO cells, and further cloned to obtain high expressors. The  $\alpha C$  deletion mutant showed collagen binding at a level comparable to that of wild type (Fig.3a). Adhesion of the  $\alpha C$  deletion mutant as a function of collagen coating concentration was tested. Adhesion to collagen of both wild type and  $\alpha C$  deletion mutant  $\alpha 2\beta 1$  was saturated at about 1  $\mu\text{g/ml}$  collagen coating concentration, indicating that the affinity to collagen is not affected by the  $\alpha C$  deletion (Fig.3b).

These results suggest that collagen binding is mediated by relatively conserved MIDAS residues, which are located on the N-terminal side of the I-domain. S153 and S155 are involved in metal coordination, and mutating these residues would disrupt metal binding to the I-domain. Q215 is part of the MIDAS face and makes main hydrogen bond to DXSXS loop. It is likely that mutating these residues block collagen binding by disrupting metal binding to the I-domain. N154, D219, and H258 have been predicted to make direct contact with collagen in the previous model (20), although the effects of mutating these residues are moderate. Y157 is totally exposed to the surface, and this residue may make direct contact with collagen. Y157 has not been predicted to make direct contact with collagen. Mutating the other residues that are predicted to be critical for collagen binding in the proposed model (L220, E256, Y285, N289, L291, N295, and K298) has no significant effect on collagen binding. Even deletion of the entire C-helix did not significantly affect collagen binding. These results support the role of the MIDAS motif in collagen binding, since many of the mutants that affect collagen binding are predicted to disrupt the MIDAS motif. However, the present results are not fully consistent with the proposed model for collagen/ $\alpha 2$  I-domain binding (20).

We have modified the collagen/ $\alpha 2$  I-domain docking model based on the present mutagenesis data (Fig. 4). Recently, short synthetic triple-helical peptide, corresponding to residues 502-516 of the collagen type I  $\alpha 1$  chain, has been shown to bind to purified  $\alpha 2\beta 1$  and recombinant  $\alpha 2$  I-domain (28). The Glu and Arg residues in the GER triplet were found to be essential for recognition by  $\alpha 2$  I-domain (28). In the current model, we first attached the glutamate side chain of the GER motif to the MIDAS  $Mg^{2+}$  ion. We then rotated the collagen to minimize the distance between the

collagen and those surface-exposed residues implicated in collagen binding (H258, Y157, D219 and N154) while maintaining the 2 Å bond between the glutamate oxygen and the Mg<sup>2+</sup> ion and avoiding other close contacts (<2.5 Å) with the protein. It was not initially possible to make favorable hydrogen bonds with all four side chains simultaneously, so the side chains were allowed to rotate about their C $\alpha$ -C $\beta$  bonds in order to make plausible hydrogen bonds with the collagen backbone carbonyl oxygens and amide nitrogens. The collagen orientation was then refined to optimize the hydrogen bonding geometry. This procedure allowed all four I-domain side chains to make reasonable hydrogen bonds to the collagen. This model predicts that the side chain of Tyr285, which projects from the C helix into the groove, makes unavoidable contact with the collagen, and that further hydrogen bonds can be made between the Tyr hydroxyl and the collagen main chain. This revised model, which is rotated about 30 degrees from the previously published model, allows the arginine from the GER motif of the preceding strand to make a salt bridge to E256. The previous model would not allow enough space for the arginine side chain without imposing unfavorable side chain torsion angles. Since mutation of E256 does not significantly block collagen binding in the present study, this salt bridge might not be energetically important. The triple helical character of a symmetric collagen trimer generates three chemically distinct strands, which we call the leading, middle, and lagging strands. Attaching either the leading or middle strand glutamate to the Mg<sup>2+</sup> ion leads to the same conclusions. Attaching the trailing strand makes a difference because there is no arginine from the preceding strand to form a salt-bridge to E256. The alternative orientation with the collagen rotated by 180 degrees is much less favorable because the arginine of the GER motif would clash sterically with the I-domain. As pointed out in our previous model, an aspartic acid

side chain in place of the GER glutamate would be too short to reach the  $Mg^{2+}$  ion without creating a large number of steric clashes. Since N154, Y157, H258 are conserved in other collagen-binding integrin I-domains ( $\alpha 1$  and  $\alpha 10$ ), it is reasonable to assume that these residues are also involved in collagen binding in these integrins (Fig. 4). This model is consistent with the observation that tyrosine and arginine are enriched in hot spots of binding energy in the protein-protein interface (33).

In the present model, the highly conserved D151 and D254 residues in the  $\alpha 2$  I-domain are buried underneath the  $Mg^{2+}$  ion and can not contact collagen directly. We have reported that mutating these residues only partially affects collagen binding to the recombinant  $\alpha 2$  I-domain fragment (13,15). Also, Bienkowska et al., reported that mutating the corresponding residues in the recombinant fragment of the vWf A3 domain does not affect collagen binding (23). However, the same mutation in the whole  $\alpha 2$  molecule completely blocks collagen binding to  $\alpha 2\beta 1$  (13,15). It is possible that cation coordination through these residues is critical for ligand binding in the I-domain of the integrin molecule, but not in similar domains in non-integrin structures (e.g., vWf). Consistently, the cation-binding site is not present in the vWf A3 domain (23,24). Further studies would be needed to clarify the role of the conserved Asp residues in integrin I-domains. Several other collagen-binding sites have been reported. A collagen binding surface on osteonectin has been mapped by mutagenesis: it consists of a flat surface 15 Å in diameter containing polar and apolar residues (34), a crucial arginine residue, and intriguingly a  $Ca^{2+}$  binding site that might be directly involved in collagen binding. Docking and mutagenesis of *Staphylococcus aureus* adhesin identified another crucial arginine and a narrow groove as the binding site for collagen (35).

The collagen binding surface on vWF-A3 has not been mapped but the structurally analogous surface lacks the charged residues found in the integrin I-domains (23,24). Further studies will be required to determine whether there are any common collagen binding mechanisms.

While this paper was under review, the crystal structure of a GER-containing collagen peptide/ $\alpha 2$  I domain complex has been solved (Emsley, J., Knight, C.G., Barnes, M.J., Farndale, R.W and Liddington, R., unpublished results). Preliminary analysis reveals that the structure is very similar to the revised model described here. Thus, the orientation and location of the collagen is as predicted, with a Glu residues from the collagen coordinating directly to the metal ion. In addition, there is an unexpected change in the C helix so that it no longer touches the collagen, in agreement with the mutagenesis results.

#### ACKNOWLEDGMENT

We thank F. Watt for antibodies and M. Cruz for sharing unpublished data. We also thank K.K. Tieu and W. Puzon-McLaughlin for excellent technical assistance.

## FIGURE LEGEND

Fig. 1: Residues/loops chosen for mutagenesis in this study.

The I-domains from integrin  $\alpha 1$ ,  $\alpha 2$ ,  $\alpha 10$ ,  $\alpha L$ ,  $\alpha M$ ,  $\alpha X$ ,  $\alpha D$ , and  $\alpha E$  subunits and the vWf A1 and A3 domains were aligned. The  $\beta$ -strands and  $\alpha$ -helices of the  $\alpha 2$  I-domain are underlined. Swapped regions of  $\alpha 2$  and  $\alpha L$  ( $\beta A$ - $\alpha 1$ : 152-157;  $\alpha 3$ - $\alpha 4$ : 213-219;  $\beta D$ - $\alpha 5$ : 257-262) are outlined in the box. The deleted region in  $\alpha 2$  ( $\alpha C$  del) is also outlined.

Fig. 2. Effects of point mutations on collagen binding

Cells stably expressing wt or mutant  $\alpha 2$  were used to determine adhesion to collagen (at a 10 or 2  $\mu g/ml$  coating concentration). Data are presented as % bound cells to collagen per % human  $\alpha 2$  positive cells to normalize  $\alpha 2$  expression. Typically 40-60% of cells are positive after selection with G-418. Previously published function-negative mutations (D151A, T221A, and D254A) are included as negative controls. These results suggest that several relatively conserved residues in the  $\beta A$ - $\alpha 1$ ,  $\alpha 3$ - $\alpha 4$ , and  $\beta D$ - $\alpha 5$  loops are critical for collagen binding.

Fig. 3: Effects of swapping/deletion mutations on collagen binding.

a) Clonal CHO cells stably expressing wild type or mutant  $\alpha 2$  were incubated in the well coated with collagen type I, or bovine serum albumin (negative control). After incubation at 37 °C for 1 h, non-adherent cells were removed and bound cells were determined by assaying endogenous phosphatase. Under the conditions used more than 80% of cells adhered to fibronectin as a positive control. MFI, mean fluorescence intensity.

b) Adhesion to collagen of wild type and the  $\alpha$ C deletion mutant  $\alpha$ 2 was determined as a function of collagen coating concentrations. The data suggest that the adhesive function of the  $\alpha$ C deletion mutant is comparable to that of wild type.

Fig. 4.: A revised docking model of the  $\alpha$ 2 I-domain and collagen.

All-atom representation of the  $\alpha$ 2 I-domain, viewed looking down onto the MIDAS face. In the top panel, residues with mutations that reduce collagen binding are in red (surface-exposed) or pink (likely to disrupt MIDAS). Residues with mutations that have no effect on collagen binding are in cyan. The  $Mg^{2+}$  ion is shown as a gray ball. The new collagen model is shown as a colored triple helical coil (blue, green and yellow) drawn through the  $C\alpha$  positions. The previous model (20) is shown as a transparent triple helical coil. Certain residues referred to in the text are labeled. In the bottom panel, residues shown in red are invariant between  $\alpha$ 1,  $\alpha$ 2 and  $\alpha$ 10 I-domains.
